#### Abstract

The Longest Common Subsequence (LCS) problem aims at finding a longest string that is a subsequence of each string from a given set of input strings. This problem has applications, in particular, in the context of bioinformatics, where strings represent DNA or protein sequences. Existing approaches include numerous heuristics, but only a few exact approaches, limited to rather small problem instances. Adopting various aspects from leading heuristics for the LCS, we first propose an exact A* search approach, which performs well in comparison to earlier exact approaches in the context of small instances. On the basis of A* search we then develop two anytime algorithms in which classical $\mathrm{A}^{*}$ iterations are alternated with beam search and anytime column search, respectively. A key feature to guide the heuristic search in these approaches is the usage of an approximate expected length calculation for the LCS of uniform random strings. Even for large problem instances these anytime A* variants yield reasonable solutions early during the search and improve on them over time. Moreover, they terminate with proven optimality if enough time and memory is given. Furthermore, they yield upper bounds and, thus, quality guarantees when terminated early. We comprehensively evaluate the proposed methods using most of the available benchmark sets from the literature and compare to the current state-of-the-art methods. In particular, our algorithms are able to obtain new best results for 82 out of 117 instance groups. Moreover, in most cases they also provide significantly smaller optimality gaps than other anytime algorithms.

Keywords: longest common subsequence problem; anytime algorithm; A* search; beam search; anytime column search

## 1. Introduction

In computer science strings are widely used for representing sequence information. Words and longer texts are naturally represented by means of strings, and in the field of bioinformatics, DNA, RNA and protein sequences, for example, play particularly important roles.

We formally define a string $s$ as a finite sequence of $|s|$ characters from a finite alphabet $\Sigma$. A frequently occurring necessity is to detect similarities between several strings in order to derive relationships and possibly predict different aspects of a set of strings. A subsequence of a string $s$ is any sequence obtained by removing arbitrary characters from $s$. A natural and common way to compare two or more strings is studying their common subsequences. More specifically, given a set of $m$ input strings $S=\left\{s_{1}, \ldots, s_{m}\right\}$, the Longest Common Subsequence (LCS) problem [31] aims at finding a subsequence of maximal length which is common for all the strings in $S$. Apart from applications in computational biology [25], this problem appears, for example, in data compression [35, 3], text editing [27], the production of circuits in field programmable gate arrays [9], and file comparison (used in the Unix command diff) [4].

For fixed $m$ polynomial algorithms based on dynamic programming (DP) are known [21] to solve the LCS problem. Standard dynamic programming approaches run in $O\left(n^{m}\right)$ time, where $n$ denotes the length of the longest input string. These exact methods become quickly impractical when $m$ grows and $n$ is not small. For a general number of input strings $m$ the LCS problem is known to be $\mathcal{N} \mathcal{P}$-hard [31]. In practice, heuristic techniques are typically used for larger $m$ and $n$. The Expansion algorithm and the BestNext heuristic [18, 24] are well known simple and fast construction heuristics, respectively. Substantially better solutions can usually be obtained by more advanced search strategies and metaheuristics. Among these are in particular many approaches that are based on Beam Search (BS), see e.g., $[6,32,36,42,15]$, and they differ in various important details such as the heuristic guidance, the branching mechanism, and the filtering.

In our recent work [14], we proposed a general BS framework for the LCS that unifies all the heuristic state-of-the-art approaches from the literature in the sense that each one can be expressed by respective configuration settings. Moreover, a novel heuristic guidance function was proposed, which approximates the expected length of a LCS for random strings. In a comprehensive experimental comparison previous methods have been compared and a new state-of-the-art BS variant was determined, which dominates the other approaches on most of the available benchmark instances. The mentioned new heuristic guidance function turned hereby out to play a crucial role.

Concerning exact approaches for the LCS problem, an integer linear programming model has been considered in [7]. It is, however, not competitive as it cannot be applied to any of the commonly used benchmark instances due to too many variables and constraints in the model. Dynamic programming approaches are reasonable for small $m$ and small $n$, but they also quickly run out of memory for larger instances and then typically return only weak solutions, if at all. Chen et al. [10] proposed the parallel FAST_LCS search algorithm, which is based on producing a special successors table to obtain all the identical pairs and their levels. Successor nodes are derived in parallel. Pruning operations are utilized to reduce the computational effort. While the algorithm is effective for a small number of input strings, it also struggles for larger $m$. Wang et al. [42] proposed another parallel algorithm called QUICK-DP, which is based on the dominant point approach and employs a fast divide-and-conquer technique to compute the dominant points. More recently, Li et al [28] suggested the Top_MLCS algorithm, which is based on a directed acyclic layered-graph model (called irredundant common subsequence graph) and parallel topological sorting strategies used to filter out paths representing suboptimal solutions. Moreover, the authors showed that the earlier dominant-point-based algorithms do not scale well to larger LCS instances, and Top_MLCS significantly outperforms them. In addition to the sequential Top_MLCS, also a parallel variant was proposed. Another
parallel space efficient algorithm based on a graph model, called the Leveled-DAG, was described by Peng and Wang [33]. It eliminates all the nodes in the layered graph that do not contribute to the construction of the LCS, and thus keeps only the nodes from the current level and some previously generated ones. In the experimental comparison, Leveled-DAG and Top_MLCS solved the same number of benchmark instances to proven optimality, but Leveled-DAG consumed less memory.

Despite these recent advances, solving practically relevant instances to proven optimality remains a substantial challenge in terms of memory and computation time, even when utilizing many parallel threads. The existing exact methods are therefore frequently not applicable in practice. As a compromise between classical exact techniques and pure heuristic approaches, anytime algorithms have been proposed [48, 47]. An anytime algorithm is supposed to fulfill the following properties: (1) It is, in principle, complete in the sense that it terminates with a proven optimal solution when enough time and memory is provided; (2) it can be terminated at almost any time and then returns a solution of reasonable quality; and (3) the solution quality improves with the given time.

Anytime algorithms thus offer to choose the trade-off between solution quality and computational requirements. Concerning the LCS problem, two anytime approaches have been proposed in the literature so far: Pro-MLCS [44] and SA-MLCS [43]. Both algorithms are based on the dominant point method [41], which features a special distance measure dist for heuristic guidance and a specific multi-dimensional data structure for checking the dominance relation of already explored nodes during the search. Algorithm ProMLCS iteratively extends a fixed number of nodes at each level in a level-by-level manner and is similar to anytime column search [39], which we will consider in more detail in Section 4.2. On the other side, SA-MLCS applies an iterative beam widening strategy in successive iterations to reduce space requirements. It differs from Pro-MLCS in the data structures utilized to maintain open nodes. A specific priority queue is realized for SA-MLCS which stores those nodes whose children have not all been expanded, further exploited in the algorithm to make use of the search information from previous iterations to improve efficiency of the SA-MLCS. Last but not least, [43] describes another memory bounded variant of SA-MLCS, called SLA-MLCS. A weakness of all these approaches is that they are not able to provide an upper bound on the solution quality and therefore no quality guarantee in case of early termination. Moreover, neither in [44] nor in [43] enough details are provided concerning the multi-dimensional data structure for checking dominance. This made it, unfortunately, impossible to re-implement the algorithms with all their details, and source code is not provided by the authors. However, in the experimental section of this work we consider the distance measure dist as an alternative heuristic guidance and we also build upon anytime column search.

Our contributions are as follows. We first propose an exact A* search for the LCS problem, which is derived from components and settings that proved already useful in heuristic BS variants as determined in our earlier studies $[15,14]$. This $\mathrm{A}^{*}$ search is shown to be effective for small instances, but as one may expect it has serious scalability issues similar to other exact methods in terms of time and memory requirements when considering larger instances. We therefore extend this A* search by applying two alternative hybrid search strategies from [16], turning the original $\mathrm{A}^{*}$ search into effective anytime algorithms for finding an LCS. Both follow the idea of interleaving traditional A* search iterations with heuristic search - either BS or anytime column search [39]-and they are labeled A* + BS and $\mathrm{A}^{*}+\mathrm{ACS}$, respectively. The $\mathrm{A}^{*}$ framework ensures completeness and provides upper bounds at any time, while the embedded heuristic search iterations rely on the heuristic
guidance function from [14] and are responsible for producing a first approximate solution quickly and improving it over time. Most importantly, the heuristic search iterations also operate on the list of open nodes of $\mathrm{A}^{*}$ search in order to avoid redundant node expansions.

In a comprehensive experimental study we evaluate the proposed approaches on various LCS benchmark sets from the literature and compare to the so far best methods' results. Earlier computational studies always considered a subset of the available benchmark sets. Concerning proven optimality, our A* search is able to solve 106 instances from the literature, which exceeds the number of solved instances by Top_MLCS by six. Moreover, in most cases our A* search is faster than Top_MLCS. For the remaining instances that cannot be solved to optimality, $\mathrm{A}^{*}+\mathrm{ACS}$ turns out to be the now leading method for most benchmark sets in respect to final solution quality. Moreover, optimality gaps are considered for larger LCS instances for the first time, and those obtained by $\mathrm{A}^{*}+\mathrm{ACS}$ are shown to be significantly better than the ones of the other considered approaches on many occasions. Most remarkably, $\mathrm{A}^{*}+\mathrm{ACS}$ was able to achieve new best known solutions for 82 different LCS instance groups, which corresponds to $\approx 70 \%$ of all the considered instance groups.

The rest of this article is organized as follows. Section 2 gives an overview on essential previous work and definitions required for the $A^{*}$ search for the LCS problem and its anytime variants. The A* search framework is then presented in Section 3, while Section 4 provides the details of the $\mathrm{A}^{*}+\mathrm{ACS}$ and $\mathrm{A}^{*}+\mathrm{BS}$ anytime algorithms. Section 5 comprises the whole computational study. Conclusions and ideas for future work are given in Section 6.

## 2. Previous Work

In this section we summarize those aspects of previous work that are needed for understanding the anytime algorithms proposed in this work. Most of this material was already covered in a more detailed way in [14], where we introduced a general BS framework for the LCS problem. Beam Search is a well known incomplete tree search method that works in a limited Breadth-First Search (BFS) manner. At each step, it maintains a set of nodes - called the beam-from the same level of the search tree. Note, in this context, that each node of the tree corresponds to a partial solution and a respective remaining subproblem, while the leaf nodes correspond to non-extensible solutions. The nodes of the current beam are expanded at each step, generating a set of nodes from the next level of the search tree. This set of extensions is denoted by $V_{\text {ext }}$. Among the nodes from $V_{\text {ext }}$, the $\beta>0$ most promising nodes are selected and form the beam of the next step, where $\beta$ is a strategy parameter called beam width. Beam Search keeps repeating these steps until the beam is empty, i.e., no further expansions are possible. The initial beam consists just of the root node of the search tree, which corresponds to the empty partial solution. The result of BS is the best solution in the final beam. The general BS framework from [14] covers all BS-based approaches from the literature known to us. In the following, after introducing some notations and additional concepts, two important topics are addressed: (1) the state graph on which both the BS approaches from the literature and the A* search proposed in this work operate, and (2) upper bound functions and a heuristic guidance function. Both upper bound functions and/or heuristic guidance functions are used in BS approaches for the selection of the nodes that are kept as the next iteration's beam.

### 2.1. Notations and Concepts

Let $n$ be the maximum length of the $m$ strings in $S=\left\{s_{1}, \ldots, s_{m}\right\}$, i.e., $n=$ $\max _{i=1, \ldots, m}\left|s_{i}\right|$. Furthermore, let $s[j], j=1, \ldots,|s|$, be the $j$-th letter of a string $s$, and let $s_{1} \cdot s_{2}$ denote the concatenation obtained by appending string $s_{2}$ to string $s_{1}$. Moreover, $s\left[j, j^{\prime}\right], j \leq j^{\prime}$, denotes the continuous subsequence of $s$ starting at position $j$ and ending at position $j^{\prime}$; if $j>j^{\prime}, s\left[j, j^{\prime}\right]$ is the empty string denoted by $\varepsilon$. Finally, let $|s|_{a}$ be the number of occurrences of letter $a \in \Sigma$ in string $s$. Henceforth, a string $s$ is called a (valid) partial solution to $S$, if and only if $s$ is a subsequence of each string in $S$, that is, a common subsequence of $S$.
Any subproblem of $S$ is defined on the basis of a so-called left position vector $p^{\mathrm{L}} \in \mathbb{N}^{m}$, with $1 \leq p_{i}^{\mathrm{L}} \leq\left|s_{i}\right|$ for $i=1, \ldots, m$. In particular, for a given $p^{\mathrm{L}}$, subproblem $S\left[p^{\mathrm{L}}\right]$ concerns the substrings $s_{i}\left[p^{\mathrm{L}},\left|s_{i}\right|\right]$ for all $i=1, \ldots, m$. In other words, $S\left[p^{\mathrm{L}}\right]$ contains the right part of each string from $S$ starting from the position indicated in the left position vector $p^{\mathrm{L}}$. Note that the original problem $S$ can be denoted by $S\left[p^{\mathrm{L}}=(1, \ldots, 1)\right]$. Given a (partial) solution $s$ to $S$-that is, a string $s$ that is a common subsequence of $S$-a subproblem $S\left[p^{\mathrm{L}}\right]$ is induced by defining $p^{\mathrm{L}}$ in the following way. For each $i=1, \ldots, m, p_{i}^{\mathrm{L}}$ is determined such that $s_{i}\left[1, p_{i}^{\mathrm{L}}-1\right]$ is the minimal-length string among all substrings $s_{i}[1, p], p=$ $1, \ldots,\left|s_{i}\right|$, that contain $s$ as a subsequence. For example, given $S=\{$ abcaac, acbaba $\}$ and the partial solution $s=$ aca, the induced subproblem $S\left[p^{\mathrm{L}}\right]$ is defined by left position vector $p^{L}=(5,5)$. Note that there is potentially more than one partial solution inducing the same subproblem, respectively, the same left position vector. In the example above, partial solution $s^{\prime}=$ aba, for example, induces the same subproblem and the same left position vector as partial solution $s=$ aca. Moreover, partial solutions inducing the same subproblem and the same left position vector may have different lengths. Considering again the example from above, substring $s^{\prime \prime}=$ aa induces the same subproblem and the same left position vector as $s$ and $s^{\prime}$.

### 2.2. State Graph for the LCS Problem

The state graph that is used by all BS variants known in the literature so far, and which will also be used by the A* search proposed in this paper, is a directed acyclic graph $G=(V, A)$, where a node $v=\left(p^{\mathrm{L}, v}, l_{v}\right) \in V$ represents the set of partial solutions that (1) have the same length $l_{v}$ and that (2) induce the same subproblem denoted by $S\left[p^{\mathrm{L}, v}\right]$ and left partition vector $p^{\mathrm{L}, v}$. An arc $a=\left(v_{1}, v_{2}\right) \in A$ between two nodes $v_{1} \neq v_{2} \in V-$ carrying label $\ell(a) \in \Sigma$-exists, if and only if the following two conditions are fulfilled:

1. $l_{v_{2}}=l_{v_{1}}+1$
2. The partial solution inducing $v_{2}$ is produced by appending $\ell(a)$ to the partial solution inducing $v_{1}$.

The root node $r$ of $G$ corresponds to the original problem $S$, which is induced by the empty partial solution denoted by $\varepsilon$. In technical terms, $r=((1, \ldots, 1), 0)$. In order to derive the successor nodes of a node $v \in V$, we first determine the subset $\Sigma_{v} \subseteq \Sigma$ of letters that can be used to feasibly extend the partial solutions represented by $v$. Obviously, $\Sigma_{v}$ consists of all letters $a \in \Sigma$ that appear at least once in each string of $S\left[p^{\mathrm{L}, v}\right]$. For each letter $a \in \Sigma_{v}$, the position of the first occurrence of $a$ in $s_{i}\left[p_{i}^{\mathrm{L}, v},\left|s_{i}\right|\right]$ is denoted by $p_{i, a}^{\mathrm{L}, v}$, $i=1, \ldots, m$. Set $\Sigma_{v}$ may frequently be reduced by identifying dominated letters: We say that letter $a \in \Sigma_{v}$ dominates letter $b \in \Sigma_{v}$ if and only if $p_{i, a}^{\mathrm{L}, v} \leq p_{i, b}^{\mathrm{L}, v}$ for all $i=1, \ldots, m$.

Dominated letters can safely be ignored since they always lead to suboptimal solutions. Let $\Sigma_{v}^{\text {nd }} \subseteq \Sigma_{v}$ be the subset of those letters that are non-dominated. Graph $G$ contains for each letter $a \in \Sigma_{v}^{\text {nd }}$ a successor node $v^{\prime}=\left(p^{\mathrm{L}, v^{\prime}}, l_{v}+1\right)$ of $v$, where $p_{i}^{\mathrm{L}, v^{\prime}}=p_{i, a}^{\mathrm{L}, v^{\prime}}+1$, $i=1, \ldots, m$. A node $v$ that has no successor node - that is, when $\Sigma_{v}^{\text {nd }}=\emptyset$-is called a non-extensible node. Now, note that any path from the root node $r$ to any node in $v \in V$ represents the feasible partial solution obtained by collecting and concatenating the labels of the traversed arcs ${ }^{1}$. Any path from $r$ to a non-extensible node represents a common subsequence of $S$ that cannot be further extended, and any longest path from $r$ to a non-extensible node represents an optimal solution to problem instance $S$.

### 2.3. Upper Bounds

The BS approaches from the literature make use of different upper bounds for the lengths of LCS (sub-)problems in order to select promising nodes for the beam of the next step. We consider here the most successful bounds. The upper bound from Blum et al. [6] was derived by tightening the bound from Fraiser [18]. Given a node $v$ representing the left position vector $p^{\mathrm{L}, v}$ and the corresponding subproblem $S\left[p^{\mathrm{L}, v}\right]$, this bound calculates the minimal number of occurrences of each letter over all the strings of subproblem $S\left[p^{\mathrm{L}, v}\right]$ and returns the sum of these, i.e.,

$$
\begin{equation*}
\mathrm{UB}_{1}(v)=\mathrm{UB}_{1}\left(p^{\mathrm{L}, v}\right)=\sum_{a \in \Sigma} \min _{i=1, \ldots, m}\left|s_{i}\left[p_{i}^{\mathrm{L}, v},\left|s_{i}\right|\right]\right|_{a} \tag{1}
\end{equation*}
$$

This bound can be efficiently determined in $O(m \cdot|\Sigma|)$ time when using a suitable data structure that is initialized in preprocessing (for more details see [15]).
A DP-based upper bound was introduced by Wang et al. [42], making use of the LCS calculation for two input strings. For each pair $\left\{s_{i}, s_{i+1}\right\} \subseteq S, i=1, \ldots, m-1$, a socalled scoring matrix $M_{i}$ is constructed in a pre-processing step, where an entry $M_{i}[p, q]$, with $p=1, \ldots,\left|s_{i}\right|$ and $q=1, \ldots,\left|s_{i+1}\right|$, stores the length of the LCS of strings $s_{i}\left[p,\left|s_{i}\right|\right]$ and $s_{i+1}\left[q,\left|s_{i+1}\right|\right]$. Given a node $v$ representing the left position vector $p^{\mathrm{L}, v}$ and the corresponding subproblem $S\left[p^{\mathrm{L}, v}\right]$, the upper bound is then calculated as

$$
\begin{equation*}
\mathrm{UB}_{2}(v)=\mathrm{UB}_{2}\left(p^{\mathrm{L}, v}\right)=\min _{i=1, \ldots, m-1} M_{i}\left[p_{i}^{\mathrm{L}, v}, p_{i+1}^{\mathrm{L}, v}\right] . \tag{2}
\end{equation*}
$$

Not considering the pre-processing step, this bound can be calculated in $O(m)$ time. As in general neither $\mathrm{UB}_{1}$ dominates $\mathrm{UB}_{2}$ nor does $\mathrm{UB}_{2}$ dominate $\mathrm{UB}_{1}$, it makes sense to also consider the combined bound $\mathrm{UB}(v)=\min \left\{\mathrm{UB}_{1}(v), \mathrm{UB}_{2}(v)\right\}$.

### 2.4. Approximate Expected Length Calculation of an LCS

Some of the BS approaches make use of a heuristic guidance function instead of an upper bound for the selection of the nodes that form the beam of the next iteration. In the following we briefly describe the one that we introduced in [14]. This heuristic guidance function is based on a DP recursion by Mousavi and Tabataba [32], which calculates the probability that any string of length $p$ is a subsequence of a uniform random string of

[^0]length $q$, for $0 \leq p, q \leq n$. Let us assume that these probabilities are stored in a matrix P with elements $\mathrm{P}[p, q] \in[0,1], 0 \leq p, q \leq n$.
The heuristic guidance function makes two strong assumptions: (1) the strings from $S$ are all uniform random strings, and (2) the input strings are independent from each other. For each sequence $x$ of length $k$ over alphabet $\Sigma$ we denote by $\operatorname{Ev}_{x}$ the event that $x$ is a common subsequence of the input strings from $S$. For any two sequences $x$ and $y$, $x \neq y$, we additionally make the simplifying assumption that the events $\mathrm{Ev}_{x}$ and $\mathrm{Ev}_{y}$ are independent (which does not hold in reality). By applying some basic laws from probability theory, the heuristic guidance function which-given a node $v$ representing the left position vector $p^{\mathrm{L}, v}$ and the corresponding subproblem $S\left[p^{\mathrm{L}, v}\right]$-approximates the expected length of a LCS in the corresponding subproblem can be stated as
\[

$$
\begin{equation*}
\operatorname{EX}(v)=l_{\min }-\sum_{k=1}^{l_{\min }}\left(1-\prod_{i=1}^{m} \mathrm{P}\left(k,\left|s_{i}\right|-p_{i}^{\mathrm{L}, v}+1\right)\right)^{|\Sigma|^{k}} \tag{3}
\end{equation*}
$$

\]

where $l_{\text {min }}=\min \left\{\left|s_{i}\right|-p_{i}^{\mathrm{L}, v}+1 \mid i=1, \ldots, m\right\}$. An extensive computational study presented in [14] has shown that this heuristic guidance function has a significant impact on finding high-quality solutions for many instances. The general conclusion was that its use in BS approaches is generally preferred over the use of upper bound functions in the context of benchmark instances in which the input strings are quasi-independent.

## 3. A* Search Framework

As mentioned before, our focus in this work is on the development of $\mathrm{A}^{*}$-based anytime algorithms for the LCS problem. A* search [23] is a well-known exact technique widely used in path-finding and planning. It belongs to the class of informed search methods, employing a best-first search strategy. Our A* search for the LCS problem operates on the state graph $G$ as defined in Section 2.2. At each iteration the most promising not-yet-processed/expanded (open) node is expanded. To this end, each node $v$ reached is evaluated by a priority function $f(v):=g(v)+h(v)$, where $g(v)$ denotes the cost of the best path from the root node $r$ to $v$ and $h(v)$ is a heuristic function that estimates the cost-to-go, the cost of the best path from $v$ to a goal node. In the context of the LCS, the cost of a path refers to its length, and a path is better the longer it is. Furthermore, any non-extensible node of the state graph represents a goal node. Good candidates for $h(\cdot)$ in the context of the LCS are upper bound functions, such as the ones discussed in Section 2.3. They never underestimate the length of the best/longest path to a goal node and are called admissible in the terminology of $\mathrm{A}^{*}$ search. Using an admissible heuristic function guarantees that an optimal solution is found when a goal node is finally selected for expansion and the search terminates. Moreover, the proposed upper bounds are monotonic, i.e., the upper bound of any extension of a node is always at most as high as the upper bound of the original node. This property guarantees that re-evaluations of already expanded nodes are never necessary. To efficiently retrieve the node with highest priority in each iteration, A* search maintains all open nodes in a priority queue $Q$. Additionally, our A* search maintains a hash map $N$ with left position vectors $p^{\mathrm{L}, v}$ as keys mapping to the respective $l_{v}$-values. By this data structure, we can efficiently recognize already reached left position vectors.
A* search starts with the initialization of $Q$, that is, $Q=\{r\}$. At each iteration, it expands the top node of $Q$ by generating the respective successor nodes. If its left position vector

```
Algorithm \(1 \mathrm{~A}^{*}\) for the LCS problem.

                \(l_{v^{\prime}} \leftarrow l_{v}+1\)
                if \(p^{\mathrm{L}, v^{\prime}} \in N\) then
                    if \(N\left[p^{\mathrm{L}, v^{\prime}}\right]<l_{v^{\prime}}\) then \(/ /\) a better path to the node was found
                        \(N\left[p^{\mathrm{L}, v}\right] \leftarrow l_{v^{\prime}}\)
                                update priority value of node \(v\) in \(Q\)
                        end if
                    else // a new node
                        \(f_{v^{\prime}} \leftarrow l_{v^{\prime}}+\mathrm{UB}\left(v^{\prime}\right)\)
                        add \(v^{\prime}\) of the priority \(f_{v^{\prime}}\) to \(Q\)
                        add \(v^{\prime}\) to \(N\)
                    end if
                end for
        end if
    end while
    return empty solution \(\varepsilon\)
```

is not already present in $N$, a successor node is added to $N$ and to $Q$. If, on the other side, the successor's left position vector is already in $N$, it is checked if the new path to $v$ is longer than the already known one. If this is the case, the $l_{v}$-value of $v$ is updated correspondingly, and the priority of $v$ (used for its ranking in $Q$ ) is adapted accordingly. The algorithm keeps expanding the top nodes of $Q$ until optimality is reached by selecting a goal node or either the memory limit or a time limit is exceeded. One potential problem is that $Q$ typically contains many nodes with the same priority value. These ties are broken by prioritizing those nodes which are farther away from the root node, i.e., the ones with higher $l_{v}$ values. Remaining ties are broken with the help of a $k$-norm of the remaining string lengths, i.e., each node is evaluated by $\kappa(v)=\left(\sum_{i=1}^{m}\left(\left|s_{i}\right|-p_{i}^{\mathrm{L}, v}+1\right)^{k}\right)^{\frac{1}{k}}$. These $\kappa(v)$-values can be seen as a rough heuristic indicator for the cost-to-go, nodes with larger values are expected to be more promising. We used $k=0.5$ in our implementation. A pseudo-code of our A* search for the LCS problem is given in Algorithm 1. Note that an alternative $\mathrm{A}^{*}$ algorithm was proposed in [42]. However, this simpler algorithm uses just the weaker upper bound function $\mathrm{UB}_{2}$ to guide the search, does not consider tie breaking, and has a larger memory footprint.

## 4. Anytime Algorithms for the LCS Problem

When faced with large-size problem instances of hard optimization problems, pure exact approaches such as DP or $\mathrm{A}^{*}$ search frequently reach their limits. Moreover, if not given enough time (or space) to terminate, these algorithms are not able to provide suboptimal solutions of reasonable quality. Therefore, the optimization community has, at some point, started to improve such algorithms by adding mechanisms that allow them to be terminated early and nevertheless provide feasible solutions of reasonable quality. The phrase anytime algorithms was used for the first time in the literature by Dean and Boddy [11, 12] in the middle of the 80 's, referring to a class of algorithms that is able to find an initial approximate solution quickly and then improves upon it over time, until optimality is finally guaranteed if enough time is given. These algorithms are nowadays widely used in planning and intelligent systems and domains such as real-time diagnosis and repair, mobile robot control, and signal interpretation. In these domains, solutions must frequently be obtained rather quickly but sometimes more time can be spent [48, 47]. Anytime algorithms are flexible in terms of time and resources used. They are designed to offer a selectable trade-off between solution quality and computational requirements.

Two important groups of anytime algorithms are those based on BS and on A* search, respectively. The BS-based anytime algorithms are generally characterized by repeated applications of BS (with a reduced beam width) in which the initial beam of a subsequent iteration is, in some way, based on nodes that were discovered but not processed in earlier iterations. One of the first approaches of that kind was proposed by Zhang [45]. This algorithm was able to reach high-quality solutions earlier than standard BS, in addition to being able to produce optimal solutions if given enough computational resources. Another example is beam stack search [46], which integrates systematic backtracking within BS. On the other side, a lot of work has been dedicated to the development of A*-based anytime approaches. Hansen and Zhou [22] presented anytime weighted A*. The main idea of this algorithm is to change the evaluation function to $f(v)=g(v)+w \cdot h(v)$, where $w \geq 1$ is a weight parameter. In general, a larger weight will yield a shorter run and cruder solution as the heuristic guidance is inflated, while smaller weights will yield better solutions at the cost of longer runtimes. Thus, the search is typically iteratively performed with decreasing weights. Likhachev et al. [29] proposed the Anytime Repairing A* (ARA*) algorithm, which extends anytime weighted $\mathrm{A}^{*}$ by reusing the results of an iteration in the subsequent one; it is therefore significantly more efficient. In order to get rid of the sensitive weight parameter, Anytime Non-parametric A* (ANA*) was proposed by Berg et al. [40]; here, the greediness of the search is adapted as the quality of the solutions found improves. Aine et al. [2] suggested Anytime Window A* (AWA*), where they set a range for the levels from which the nodes of the corresponding open lists are only allowed to be expanded and by which they enforce convergence to a sub-optimal solution at each iteration. This range (i.e., window) is adapted at each iteration to produce an improved solution. A memory bounded variant of AWA*, called MAWA*, was proposed in [37].

Later, Vadlamundi et al. [39] described Anytime Column Search (ACS). Here, the nodes of the state graph are organized into layers. The algorithm maintains a separate priority queue for each of these layers. At each iteration of ACS, which is performed in a level-by-level manner, up to $\beta$ of the best nodes of each level of the state graph are expanded. An algorithm based on a similar idea was presented by Kao et al. [26]. We will build upon ACS in Section 4.2, where we will also introduce it in more detail. More recently, Vadlamundi et al. [38] proposed Anytime Pack Search (APS), which maintains a container
of pack $>0$ nodes-where pack is a parameter of the algorithm-and a priority queue $Q$ of not-yet-expanded nodes. At each iteration, standalone BS runs are successively performed for which the initial beam is composed of the first pack nodes from the top of priority queue $Q$, until $Q$ becomes empty. The authors showed APS to be a state-of-the-art approach for three different problem domains [38]. Therefore, we decided to consider APS for comparison purposes also in the current work for finding a LCS.

The two new anytime algorithms that we present in this work for the LCS problem are based on the A* framework from Section 3. Our main idea is to embed efficient heuristic approaches into the $\mathrm{A}^{*}$ framework which are repeatedly executed inbetween regular $\mathrm{A}^{*}$ iterations. Our A* anytime variants-apart from providing excellent solutions-are able to return proven gaps at almost any time when terminated prematurely.

## 4.1. $A^{*}+$ BS Approach

Since BS approaches are the state-of-the-art heuristic techniques for the LCS problem but A* search is more promising when it comes to solving smaller instances to proven optimality, it seems sensible to combine A* search with BS into an anytime search method denoted by $\mathrm{A}^{*}+\mathrm{BS}$. We presented the basic idea of such a hybrid search strategy originally in [16], where it was applied to the longest common palindromic subsequence problem. At the start of $A^{*}+B S$, a run of $B S$ with small width is performed for which the beam is initialized with the root node $r$. This initial BS run takes place to obtain a first reasonable approximate solution (and thus a primal bounds) rather quickly. Then the algorithm proceeds by iteratively applying the following scheme. First, $\delta$ traditional iterations of A* search are performed, with $\delta>0$ being a strategy parameter. Second, a BS run is applied in which the first beam is initialized with the top node of $Q$. The algorithm stops once optimality is proven or a memory limit, respectively time limit, is exceeded. To avoid redundant recalculations, all the embedded BS calls and the $\mathrm{A}^{*}$ search act on the same search tree. All non-expanded nodes encountered during a BS run are used to update the hash map $N$ and are inserted into the priority queue $Q$ (if not already there). Moreover, if a new best path to some node is encountered within any BS iteration, an update of the corresponding node in $N$ is performed by changing the key to the new $l_{v}$-value, and the node is then added into the corresponding beam, that is, the nodes which were already encountered during the search are allowed to be added into $V_{\text {ext }}$.
A pseudo-code for $\mathrm{A}^{*}+\mathrm{BS}$ is provided in Algorithm 2. Parameters $\beta>0$ (beam width of BS ) and $\delta>0$ (frequency of BS applications) control the balance between BS and classical A* search iterations and thus the emphasis on improving the primal bound versus the dual bound, respectively. Beam search makes use of a function Filter ( $V_{\text {ext }}, k_{\text {filter }}$ ) for filtering dominated successor nodes at each step. This procedure works as follows. Up to $k_{\text {filter }}$ of the most promising nodes are selected from $V_{\text {ext }}$ as a reference set. Then, all other nodes from $V_{\text {ext }}$ that are dominated by at least one of these reference solutions are removed from $V_{\text {ext }}$. If $k_{\text {filter }}=0$, no filtering is applied. Moreover, the employed BS uses the upper bound UB from Section 2.3 in order to choose up to $\beta$ nodes for the beam of the next step. Finally, note that the A* search framework ensures completeness of the $\mathrm{A}^{*}+\mathrm{BS}$ algorithm and provides proven gaps at any time.

The procedure ExpandNode for the expansion of a node and updating the respective data structures is provided in Algorithm 3 (for now, disregard the lines marked to be relevant only for $\left.\mathrm{A}^{*}+\mathrm{ACS}\right)$. If the node to be expanded is a goal node, it is checked if it yields a new best solution. If this is the case, $s_{\text {best }}$ is updated accordingly. Moreover, if the length

```

    consecutive A* iterations; \(k_{\text {filter }} \geq 0\) : extent of filtering
    \(s_{\text {best }} \leftarrow \varepsilon\)
    \(p^{\mathrm{L}, r} \leftarrow(1, \ldots, 1)\)
    \(r \leftarrow\left(p^{\mathrm{L}, r}, 0\right)\)
    \(N\left[p^{\mathrm{L}, r}\right]=0\)
    \(Q \leftarrow\{r\}\)
    opt \(\leftarrow\) false
    while not opt and neither memory limit nor time limit exceeded do
        \(B \leftarrow\) pop the \(\beta\) top nodes from \(Q\)
        while \(B \neq \emptyset\) do
            // perform BS:
            for all \(v \in B\) do
                    ExpandNode \((v) / /\) see Alg. 3
                    store respective children of \(v\) in \(V_{\text {ext }}\)
            end for
            Filter \(\left(V_{\text {ext }}, k_{\text {filter }}\right) / /\) filter dominated nodes from \(V_{\text {ext }}\)
            \(B \leftarrow \operatorname{Reduce}\left(V_{\text {ext }}, \beta\right)\)
        end while
        iter \(\leftarrow 0\)
        while iter \(<\delta\) and neither memory limit nor time limit exceeded do
            // perform A* iteration:
            \(v \leftarrow\) get top node from \(Q\)
            remove \(v\) from \(Q\)
            ExpandNode ( \(v\) ) // see Alg. 3
            iter \(\leftarrow\) iter +1
        end while
    end while
    return \(s_{\text {best }}\)
```

of the so-far best solution $s_{\text {best }}$ is greater or equal to the $f$-value of the top node in $Q$, the flag opt is set to true, meaning that the search terminates with proven optimality of $s_{\text {best }}$.

## 4.2. $A^{*}+A C S$ Approach

As mentioned above, each BS run in $\mathrm{A}^{*}+\mathrm{BS}$ starts from the current top node of $Q$. This means that each BS run only deals with extensions of this single node, and consequently the search space is rather restricted. In particular, many other highly promising nodes at different levels of the state graph may have already been identified, but they are ignored. In order to deal with this potential short-coming, we developed an alternative approach in the line of [16] in which BS runs are exchanged by major iterations of the above already mentioned Anytime Column Search (ACS) [39]; this hybrid approach is henceforth labeled $\mathrm{A}^{*}+\mathrm{ACS}$.

Anytime column search is an iterative algorithm which maintains for each level $j$ of the state graph a priority queue $Q_{j}$ that stores - in the context of the LCS problem-all open nodes $v$ with $l_{v}=j, j=0, \ldots, j_{\max }, j_{\max }=\mathrm{UB}(r)$. Initially, $Q_{0}$ contains the root node $r$

```
Algorithm 3 ExpandNode \((v)\).
    Input: a node \(v\) to be expanded; a flag parameter
    Uses resp. updates: \(s_{\text {lcs }}, N, Q\) and if called from \(\mathrm{A}^{*}+\mathrm{ACS}, Q_{j}, j=0, \ldots, j_{\max }\);
    if \(\Sigma_{v}^{\text {nd }}=\emptyset\) then \(/ / v\) is a complete node
        \(s \leftarrow\) derive the non-extensible solution corresponding to \(v\)
        if \(\left|s_{\text {lcs }}\right|<|s|\) then // update best sol.
            \(s_{\text {lcs }} \leftarrow s\)
        end if
    else
        for all \(a \in \Sigma_{v}^{\text {nd }}\) do \(/ /\) expand \(v\)
            \(p_{i}^{\mathrm{L}, v^{\prime}} \leftarrow p_{i, a}^{\mathrm{L}, v^{\prime}}+1, i=1, \ldots, m\)
            \(l_{v^{\prime}} \leftarrow l_{v}+1\)
            if \(p^{\mathrm{L}, v^{\prime}} \in N\) then
                if \(N\left[p^{\mathrm{L}, v^{\prime}}\right]<l_{v^{\prime}}\) then \(/ /\) a better path to the node encountered
                \(N\left[p^{\mathrm{L}, v^{\prime}}\right] \leftarrow l_{v^{\prime}}\)
                update priority of the corresponding node in \(Q\);
                if called from \(\mathrm{A}^{*}+\mathrm{ACS}\) then
                    move node \(v^{\prime}\) from \(Q_{l_{v}}\) to \(Q_{l_{v^{\prime}}}\)
                        end if
                end if
            else // create new node
                add \(v^{\prime}\) to \(N\)
                \(f_{v^{\prime}} \leftarrow l_{v^{\prime}}+\mathrm{UB}\left(v^{\prime}\right)\)
                add \(v^{\prime}\) with priority \(f_{v^{\prime}}\) to \(Q\)
                if called from \(A^{*}+\mathrm{ACS}\) then
                \(e_{v^{\prime}} \leftarrow \operatorname{EX}\left(v^{\prime}\right)\)
                add \(v^{\prime}\) with priority \(e_{v^{\prime}}\) to \(Q_{l_{v^{\prime}}}\)
                end if
            end if
        end for
    end if
    if \(\left|s_{\text {lcs }}\right| \geq \max _{v \in Q} f(v)\) then
        opt \(\leftarrow\) true
    end if
```

and the other priority queues are empty. Each major iteration of ACS considers all levels $j=0, \ldots, j_{\max }$ with non-empty queues $Q_{j}$ in turn, and expands $\beta$ nodes (or less if $Q_{j}$ is shorter. The procedure terminates with an optimal solution once all priority queues are empty. Note that ACS in general finds heuristic solutions very quickly since each major iteration identifies usually at least one non-extensible heuristic solution.
The main idea for combining $A^{*}$ with $A C S$ consists again in interleaving classical $A^{*}$ iterations with major ACS iterations. Hereby, $A^{*}$ keeps working on the basis of priority list $Q$ and the priority function that utilizes the upper bound function $\mathrm{UB}(v)$. In this way, the whole approach will maintain the completeness of classical A* search and $\max _{v \in Q} f(v)$ always is a true upper bound for the optimal solution value. In contrast to $Q$, the heuristic guidance function EX from Section 2.4 is used as sorting criterion for the nodes in the level-specific ACS-queues $Q_{j}$. Remember that EX is usually a more promising guidance to find good heuristic solutions, but as it is no valid upper bound, it cannot be used
for proving optimality. Moreover, note that changes made in priority queue $Q$ must be accompanied by corresponding changes in priority queues $Q_{j}$ and vice versa. To enable a direct lookup of priority queue entries for a given node, we make use of the corresponding hash map $N$.

The pseudo-code of the $\mathrm{A}^{*}+\mathrm{ACS}$ is presented in Algorithm 4. Note that at each entry of the main while loop (lines 8-32), the algorithm first executes one major iteration of ACS (lines $10-31$ ) and afterwards $\delta$ classical A* iterations (lines $22-28$ ). Note that, just like $A^{*}+B S$, the algorithm potentially makes use of filtering when case $k_{\text {filter }}>0$ during the major iterations of ACS (line 21). The only difference is that nodes removed from $V_{\text {ext }}$ due to filtering are not only removed from $N$ and $Q$ but also from the corresponding queue $Q_{j}$. Parameters $\beta$ and $\delta$ play the same role as in $\mathrm{A}^{*}+\mathrm{BS}$, namely, controlling the balance between finding good heuristic solutions and improving the dual bound over time. Finally, $\mathrm{A}^{*}+\mathrm{ACS}$ terminates either with a proven optimal solution, or once the memory limit or the time limit is exceeded, returning the best non-extensible solution found up to this point.

## 5. Experimental Evaluation

In the following we first provide a summary of the algorithms that are considered for the experimental evaluation. These are our two anytime algorithms (1) $\mathrm{A}^{*}+\mathrm{BS}$ and (2) $\mathrm{A}^{*}+\mathrm{ACS}$, (3) the APS algorithm from [38], which is one of the state-of-the-art anytime variants from literature that we implemented for comparison purposes, and (4) A* + ACSdist which is the variation of $\mathrm{A}^{*}+\mathrm{ACS}$ in which the heuristic guidance function EX is replaced by the dist(•) estimation from Pro-MLCS [44] and SA-MLCS [43]. Unfortunately, we were not able to do a full comparison to Pro-MLCS and SA-MLCS as the codes could not be obtained from the authors and the description of the special multidimensional tree data structure for determining dominated solutions is insufficient for a re-implementation. However, $\mathrm{A}^{*}+$ ACS-dist without the classical $\mathrm{A}^{*}$ iterations in (i.e., when setting $\delta=0$ ) almost corresponds to Pro-MLCS except that instead of the multidimensional data structure from [44], Filter $(\cdot, \cdot)$ is used for filtering dominated solutions.
All algorithms were implemented in $\mathrm{C}++$ and the experiments were conducted in singlethreaded mode on a machine with an Intel Xeon E5-2640 processor with 2.4 GHz allowing a maximum of 32 GB of memory. The maximum computation time for each run was limited to 900 seconds. The considered algorithms were evaluated by the quality of the best solutions they provided and by the percentage gaps, which are calculated at time $t>0$ as $\operatorname{gap}(t):=\frac{\mathrm{ub}(t)-\left|s_{\text {best }}(t)\right|}{\mathrm{ub}(t)} \cdot 100 \%$, where $s_{\text {best }}(t)$ denotes the best solution found up to time $t$ and $\mathrm{ub}(t)$ denotes the upper bound on the length of an optimal solution obtained from the $f$-value of the top node in $Q$ at time $t$ (or the optimal solution value when already available).

### 5.1. Benchmark Instances

The related literature on the LCS problem offers six public benchmark sets for the LCS problem. We used all of them for the experimental evaluation here. The BL benchmark [7] consists of 450 problem instances grouped by different values for the number of input strings $(m)$, the maximum length of the input strings $(n)$, and the alphabet size $(|\Sigma|)$. For each combination of $m, n$, and $|\Sigma|$ the set offers ten instances generated uniformly at

```

    \(N\) : hash map for all reached left position vectors with the lengths of the longest paths;
    \(Q\) : priority queue of not yet expanded nodes; \(Q_{j}\) : priority queues maintained for each
    level \(j\) of the state graph; \(\beta>0\) : a beam width; \(\delta>0\) : amount of consecutive \(\mathrm{A}^{*}\)
    iterations; \(k_{\text {filter }} \geq 0\) : extent of filtering
    \(s_{\text {best }} \leftarrow \varepsilon\)
    \(p^{\mathrm{L}, r} \leftarrow(1, \ldots, 1)\)
    \(r \leftarrow\left(p^{\mathrm{L}, r}, 0\right)\)
    \(N\left[p^{\mathrm{L}, r}\right]=0\)
    \(Q \leftarrow\{r\} ; Q_{0} \leftarrow\{r\}\)
    opt \(\leftarrow\) false
    while not opt and neither memory limit nor time limit exceeded do
        \(l e v \leftarrow 0\)
        while \(l e v<j_{\max }\) do
            // perform ACS iteration:
            \(b \leftarrow 0\)
            \(V_{\text {ext }} \leftarrow \emptyset\)
            while \(Q_{\text {lev }} \neq \emptyset\) and \(b<\beta\) do
                \(v \leftarrow\) get the top node from \(Q_{\text {lev }}\)
                remove \(v\) from \(Q_{\text {lev }}\) and \(Q\)
                ExpandNode \((v) / /\) see Alg. 3
                Store respective children of \(v\) in \(V_{\text {ext }} \quad / /\) keep track of nodes for filtering
                \(b \leftarrow b+1\)
            end while
            Filter \(\left(V_{\text {ext }}, k_{\text {filter }}\right) \quad / /\) filter dominated nodes from \(V_{\text {ext }}\)
            \(l e v \leftarrow l e v+1\)
        end while
        iter \(\leftarrow 0\)
        while iter \(<\delta\) and neither memory limit nor time limit exceeded do
            // perform \(A^{*}\) iteration:
            \(v \leftarrow\) top node from \(Q\)
            remove \(v\) from \(Q\) and \(Q_{l_{v}}\)
            ExpandNode \((v) / /\) see Alg. 3
            iter \(\leftarrow\) iter +1
        end while
    end while
    return \(s_{\text {best }}\)
```

random. Furthermore, Rat and Virus are two benchmarks with a biological background, consisting of 20 instances each. Random is another rather small benchmark set consisting of 20 randomly generated instances. The latter three benchmark sets were introduced in [34]. Moreover, benchmark set ES, which was introduced in [17], is a large set with 600 instances grouped by different combinations of values for $m, n$, and $|\Sigma|$, where each group includes 50 instances. Last but not least, benchmark set BB-introduced in [5]-consists of 800 artificially created instances. These were generated in a way such that input strings have a larger similarity to each other than to random strings: Given $m,|\Sigma|$, and an additional parameter $l>0$, first a base string of length $l$ was generated uniformly at random over alphabet $\Sigma$. Then, each of the $m$ strings of the instance were derived by passing over
the base string and removing each character with a probability of $10 \%$. Thus, an input string of an instance with $l=1000$ is, on average, of length 900 . We only considered the 80 largest instances from this set, based on $m \in\{10,100\}$ and $|\Sigma| \in\{4,8,16,32\}$ and $l=1000$. There are ten instances for each combination of $m$ and $|\Sigma|$. Note that the instances in this last set are the only ones with a clear relation between the input strings, that is, where input strings are not independent of each other.

### 5.2. Tuning of the Algorithms' Parameters

In order to ensure a fair comparison, the parameters of all considered algorithms were tuned by irace [30]. This tuning took place under the same conditions (computation time limit: 900 seconds; memory limit: 32 GB ) as later the final experimental evaluation. After conducting some preliminary experiments, we decided to use the following domains for the values of the parameters for the tuning:

$$
\begin{aligned}
& \text { - } \delta \in\{0,1,10,50,100,500,1000,5000,10000,20000,50000\} \\
& \text { - } k_{\text {filter }} \in\{0,1,10,50,100,500,1000,5000,10000,+\infty\} \\
& \text { - } \beta \in\{1,50,100,500,1000,5000,10000,20000\}
\end{aligned}
$$

Since the parameter pack of APS refers to the beam width of that algorithm, we chose the same domain for pack and $\beta$. As we expected potentially stronger differences in suitable settings for the dependent instances BB and the quasi-independent other instances, we decided to apply tuning for these two instance categories separately. We used 40 additional randomly generated instances for the tuning process aimed for quasi-independent instances. The budget of irace was set to 5000 optimization runs in this case. On the other side, we generated 20 additional dependent instances for tuning purposes, in the same way as reported in [5]. The budget of irace was set to 1000 optimization runs in this second case. In addition to the separation concerning the instance type - quasiindependent versus dependent - we applied for each instance type two tuning runs with different aims. One of these tuning runs aimed for final solution quality, and the other one for small dual gaps. The results of these four tuning runs are reported in the four sub-tables of Table 1.

Concerning the tuning results for the quasi-independent instances, note that a higher beam size $\beta$ is necessary when aiming for solution quality. On the other hand, when we focus on small dual gaps, the amount of A* iterations ( $\delta$ ) has to be significantly increased for all algorithms in comparison. This result appears conclusive when considering that classical $A^{*}$ iterations are primarily important for improving the dual bound. Concerning the tuning results for the dependent instances, we can also notice the requirement of a higher value for $\delta$ when aiming for small gaps. Rather interesting is the large value required for $\beta$ in the case of $\mathrm{A}^{*}+\mathrm{BS}$ and APS when aiming for solution quality. In contrast, the tuning procedure has yielded a lower beam size for algorithms $\mathrm{A}^{*}+\mathrm{ACS}$ and $\mathrm{A}^{*}+$ ACS-dist.

### 5.3. Experimental Evaluation: Exact Solving with Classical A* Search

Initial tests indicated that our classical A* search is only meaningfully applicable to the smallest instances of the benchmark sets, that is, the instances with string length $n=100$ from set BL. The corresponding results can be found in Table 3, in which we compare the proposed $\mathrm{A}^{*}$ approach to the exact solver Top_MLCS [28]. In our comparison we

Table 1: Tuning results.
(a) Tuning for solution quality on quasi-independent instances.

| Algorithm | $\mathrm{A}^{*}+\mathrm{BS}$ | $\mathrm{A}^{*}+\mathrm{ACS}$ | $\mathrm{A}^{*}+$ ACS-dist | APS |
| :--- | ---: | ---: | ---: | ---: |
| Parameter | 50 | 1 | 100 | - |

| pack |  |  |  |  |

made use of the original implementation of Top_MLCS provided by the authors ${ }^{2}$. We remark that Top_MLCS can effectively exploit a parallel hardware architecture, but we performed it in single threaded mode in order to ensure a fair comparison with our A* approach. Besides the instance characteristics, Table 3 lists average solution lengths $\overline{|s|}$, average times $\bar{t}$ in seconds until proven optimality has been reached, and the number of instances that could be solved to optimality \#opt (out of ten per line) for both approaches.

From Table 3 it can be observed that all problem instances with $|\Sigma| \geq 12$ are solvedby both algorithms - to proven optimality, and runtimes are typically only a fraction of a second. However, $\mathrm{A}^{*}$ needs significantly less time especially for the instances with $|\Sigma|=12$. Additionally, our A* approach solved six (out of ten) instances with $|\Sigma|=4$ and $m=10$ to proven optimality ${ }^{3}$, while Top_MLCS was not able to do so due to running out of memory. None of the instances with $|\Sigma|=4$ and $m \geq 50$ could be solved to optimality by the two algorithms due to the memory limit.

In summary, $\mathrm{A}^{*}$ is able to solve 106 instances from the literature to proven optimality. At this point we would like to stress that the mixed integer linear programming solver

Table 3: Classical A* search: average results for benchmark BL, $n=100$.

CPLEX in version 12.9 applied to the LCS model from [7] could not solve any of these instances due to a too large number of variables and constraints.

### 5.4. Experimental Evaluation: Anytime Algorithms

In contrast to the classical A* search, the anytime algorithms studied in this work are able to yield meaningful results on all problem instances. Remember that we aim to compare $\mathrm{A}^{*}+\mathrm{BS}$ and $\mathrm{A}^{*}+\mathrm{ACS}$ with APS and $\mathrm{A}^{*}+\mathrm{ACS}$-dist. Additional reason why the ProMLCS [44] and SA-MLCS [43] are not considered in this comparison is because they are not designed for providing gaps upon premature termination. Moreover, we would like to emphasize that - as observed in [14]- the main factor for obtaining high quality solutions is the heuristic guidance function. For this reason we study algorithm $\mathrm{A}^{*}+\mathrm{ACS}$-dist which makes use of the heuristic guidance function dist $(v)=\sum_{i=1}^{m} p_{i}^{\mathrm{L}, v}$ from Pro-MLCS and SA-MLCS. As already mentioned, when setting $\delta=0$ in $\mathrm{A}^{*}+\mathrm{ACS}$-dist, we get reasonably close to the original Pro-MLCS algorithm.
In the following we report on results both concerning the obtained (average) solution quality and (average) gaps. For improving the readability result tables for benchmark sets Rat, Virus, ES, and BB are given in the main text, whereas the tables for Random and BL are provided in Appendix A. More specifically, the results concerning solution quality of the first four data sets can be found in Tables $4-7$, while the corresponding results concerning the gaps are presented in Tables $8-11$. The first three table columns indicate the characteristics of the considered sub-groups of the benchmark sets in terms of $|\Sigma|, m$, and $n$. Subsequently, the results of the four algorithms are presented. Each of these four blocks consists of four columns listing the following information: the average solution quality $(\overline{|s|})$, the average gaps $(\overline{g a p}[\%])$, the average time at which the best solution was found $\left(\overline{t_{\text {best }}}[s]\right)$, and the average total runtime $(\bar{t}[s])$. The tables showing the results with the parameter settings aiming for solution quality have an additional column labeled lit. best that reports the best-known result from the literature for the respective instance, or instance group (without considering the results from the current work). Asterisks in the solution quality column indicate that the best-known result from the literature was beaten. The best result concerning the comparison of the four algorithms considered in this work is always

Table 7: BB benchmark. Results when aiming for solution quality (averages over ten instances per row).
indicated in boldface. Note that in tables presenting results obtained with parameter settings aiming for solution quality, this concerns the columns on the average solution quality. While in tables presenting results obtained with parameter settings aiming for small gaps, this concerns the columns listing the average gaps.

Table 11: BB benchmark. Results when aiming for small gaps (averaged over ten instances per row).

A study of the numerical results allows to draw the following conclusions:

- $A^{*}+A C S$ generally outperforms the three competitors in terms of solution quality in the context of instances with quasi-independent input strings (that is, benchmark sets Rat, Virus, Es, Random and BL). The only exception is benchmark set BB, in which instances consist of dependent input strings. The reason for this behavior is clearly that the heuristic guidance function $\operatorname{EX}()$ works in general very well for instances with quasi-independent input strings, while it tends to mislead for instances with related input strings. Observe in Table 7 that the performance of $A^{*}+A C S$ and of $\mathrm{A}^{*}+$ ACS-dist strongly decreases, especially when the instances consist of many input strings $(m=100)$. A more visual presentation of the results is provided in Figures 5-8 in Appendix B, where the improvement of $\mathrm{A}^{*}+\mathrm{ACS}$ over the three competitors is shows in percent.

Figure 2: Critical difference plots concerning the obtained gaps.

- In order to check the statistical significance of differences, Friedman's test was performed simultaneously for all four anytime approaches. Given that in all cases the test rejected the hypothesis that the algorithms perform equally, pairwise comparisons were performed using the Nemenyi post-hoc test [13]. The outcome is shown in Figure 1 by means of so-called critical difference plots, one for each benchmark set. In short, each algorithm is positioned in the horizontal segment according to its average ranking concerning the considered set of instances. Then, the critical difference (CD) is computed for a significance level of 0.05 and the performance of those algorithms that have a difference lower than CD are considered as equal - that is, no difference of statistical significance can be detected. This is indicated in the graphics by horizontal bars joining the respective algorithms. Figure 1 shows that $\mathrm{A}^{*}+$ ACS produces significantly better results concerning solution quality for benchmark sets Rat, Virus, and BL. The differences observed for benchmark sets Random and ES are statistically not significant (despite the fact that $\mathrm{A}^{*}+\mathrm{ACS}$ produces new state-of-the-art results in 13 out of 20 , and in 10 out of 12 cases, respectively).
- Just like classical $\mathrm{A}^{*}$, both $\mathrm{A}^{*}+$ ACS-dist and $\mathrm{A}^{*}+\mathrm{ACS}$ are able to prove optimality for the instances of benchmark set BL with $n=100$ and $|\Sigma| \geq 12$. This is indicated by entries with value 0.0 in columns with heading $\overline{g a p}[\%]$ (see Table 13). However, as expected, more computation time is needed than by $\mathrm{A}^{*}$.
- $\mathrm{A}^{*}+\mathrm{ACS}$ does not only beat the competitors we considered here. It performs also very favorably in comparison to purely heuristic state-of-the-art approaches from the literature. This can be observed by comparing the performance of $\mathrm{A}^{*}+\mathrm{ACS}$ with the last columns in Tables 4-7 and Tables 12-13 which contain the so far best known results from the literature ${ }^{4}$. Overall $\mathrm{A}^{*}+\mathrm{ACS}$ was able to obtain new best-known results in 82 out of 117 cases (table rows).
- For what concerns the performance of the four algorithms with respect to the produced gaps - see Tables 8-11 and Tables 14-15 (from Appendix A) -it can be observed that-also in this case - $\mathrm{A}^{*}+\mathrm{ACS}$ generally outperforms the competing algorithms. This is with the exception of benchmark set BB, where no clear tendency can be identified. The statistical significance of this conclusion is tested in the same way as done for the case of aiming for solution quality. The corresponding critical

[^2]difference plots are shown in Figure 2. Moreover, the improvements of $\mathrm{A}^{*}+\mathrm{ACS}$ over the competitors are graphically shown in Figures 9-12 (Appendix B).

- Nevertheless, observe that $\mathrm{A}^{*}+$ ACS-dist often produces better final gaps than $\mathrm{A}^{*}+\mathrm{ACS}$ for instances with a low number of input string. This is the case, for example, for instances with $n=10$ from benchmark set BL; see Table 15 and Figure 9. A possible explanation for this behavior is as follows. On the one hand, the heuristic guidance function dist $(\cdot)$ performs rather well for instances with a low number of input strings (that is, a low $m$-value), which means that $\mathrm{A}^{*}+$ ACS-dist will not have a major disadvantage with respect to $\mathrm{A}^{*}+\mathrm{ACS}$ in those cases. On the other hand, dist $(\cdot)$ requires less computation time than the EX function used by $\mathrm{A}^{*}+\mathrm{ACS}$. This implies that $\mathrm{A}^{*}+$ ACS-dist is able to perform more node expansions than $\mathrm{A}^{*}+\mathrm{ACS}$ within the allowed computation time, which leads to better upper bounds.

### 5.5. Comparison of the Algorithms' Anytime Behavior

So far we have only studied the final results of the algorithms for what concerns solution quality and gaps. However, in the context of anytime algorithms, another important aspect to take into account is their anytime behavior. In order to visualize the anytime behavior of the algorithms, we plot the evolution of the solution quality, respectively the gaps, over time (either averaged over all problem instances of the same specifications, or averaged over multiple runs for single problem instances, depending on the benchmark set). The plots concerning solution quality are shown, for seven representative cases, in Figure 3, while the ones concerning the gaps are shown, for the same seven cases, in Figure 4. In addition to the curves showing the average behavior, these graphics also contain boxplots-shown every 200 seconds - indicating the variability of the algorithm performance.

The following observations can be made concerning the anytime plots on solution quality:

- $A^{*}+\mathrm{ACS}$ generally finds solutions of higher quality than the other algorithms in early stages of the search process. The main reason for this is clearly the heuristic guidance function EX() which is utilized in $\mathrm{A}^{*}+\mathrm{ACS}$.
- Notice also that $\mathrm{A}^{*}+\mathrm{ACS}$ is able to find improving solutions more frequently than $A^{*}+$ BS or APS. For these latter algorithms it seems much harder to find improving solutions at later stages of the search process. Even though A* + ACS-dist can be said to generally outperform APS and $\mathrm{A}^{*}+\mathrm{BS}$, it can not match the performance of $\mathrm{A}^{*}+$ ACS. It can also be observed that the compared algorithms find improving solutions in general more frequently when the alphabet size is rather small.
- APS and $\mathrm{A}^{*}+\mathrm{BS}$, which make both use of an embedded BS to find heuristic solutions, show a similar evolution of solution quality over time. It is noticeable that a rather large beam size $\beta$ is required to achieve the best possible anytime performance within the given computation time.

Concerning the anytime performance of the algorithms with respect to the gaps we can make the following observations:

- For the smallest ones of the considered instances - that is, the instances from benchmark set BL with $n=100-\mathrm{A}^{*}+\mathrm{BS}$ shows the best evolution of the obtained gaps (see Figure 4a). This is for the following two reasons: (1) the parameter values identified by our tuning process allow a significant amount of A* iterations, which is

(a) Benchmark set BL: 10 instances with (b) Benchmark set BL: 10 instances with $|\Sigma|=4, m=10, n=100$.

$$
|\Sigma|=12, m=50, n=1000
$$

(c) Benchmark set Virus: instance $|\Sigma|=4$, (d) Benchmark set Rat: instance $|\Sigma|=4$, $m=40, n=600$.

$$
m=100, n=600
$$

(e) Benchmark set Random: instance $|\Sigma|=$ (f) Benchmark set ES: 50 instances with $20, m=10, n=600$. $|\Sigma|=2, m=100, n=1000$.

(g) Benchmark set BB : 10 instances with

$$
|\Sigma|=2, m=100, n=1000 .
$$

Figure 3: Comparison of the algorithms' anytime behavior concerning solution quality.

(a) Benchmark set BL: 10 instances with (b) Benchmark set BL: 10 instances with $|\Sigma|=4, m=10, n=100$. $|\Sigma|=12, m=50, n=1000$.

(c) Benchmark set Virus: instance $|\Sigma|=4$, (d) Benchmark set Rat: instance $|\Sigma|=4$, $m=40, n=600$.

$$
m=100, n=600 .
$$

(e) Benchmark set Random: instance $|\Sigma|=$ (f) Benchmark set ES: 50 instances with $20, m=10, n=600$. $|\Sigma|=2, m=100, n=1000$.

(g) Benchmark set BB: 10 instances with

$$
|\Sigma|=2, m=100, n=1000
$$

Figure 4: Comparison of the algorithms' anytime behavior concerning gaps.
crucial for obtaining a favorable evolution of the gaps, and (2) near-optimal solutions are easily obtained for these instances by any of the algorithms.

- Concerning the remaining medium-size and large-size instances, $\mathrm{A}^{*}+\mathrm{ACS}$ shows a better anytime performance concerning the gaps for the Virus, Rat, Random, and ES benchmarks; see Figures 4b-4f. This is because the ACS-iterations, even with a rather low value of $\beta$, are still able to find rather high-quality primal solutions, while a significantly increased number of $\mathrm{A}^{*}$-iterations (in comparison to the parameter setting used when aiming for solution quality) provides improved upper bounds. In this sense, $\mathrm{A}^{*}+\mathrm{ACS}$ is an algorithm that is much better balanced than the competitors.
- In the case of small alphabet sizes, $\mathrm{A}^{*}+\mathrm{ACS}$-dist is not able to keep up with the performances of the other algorithms (see Figures 4c and 4d). Mainly responsible for this is the heuristic function dist(•), which provides a weaker guidance than in particular EX for finding good primal bounds, especially in the case of small alphabet sizes.
- APS and $\mathrm{A}^{*}+\mathrm{BS}$ show a similar behavior concerning the evolution of the average gaps over time. The necessity of working with a large beam width $(\beta)$ hinders the evolution of the gap since the search is mainly focused on improving solution quality and less on improving the upper bound.

## 6. Conclusions and Future Work

We presented an exact $\mathrm{A}^{*}$ algorithm for the LCS problem based on the general search framework for the problem proposed in our earlier study, which combines features of various other heuristic techniques. This $\mathrm{A}^{*}$ search makes use of the combination of two previously known upper bound functions for the length of the LCS and is able to solve instances of up to $n=100$ and $|\Sigma| \geq 12$ to proven optimality ( 106 instances from the literature are solved to optimality), most of them in a fraction of a second. For larger or more complex instances, however, the exact $\mathrm{A}^{*}$ search soon either runs out of memory or requires substantially more time. Therefore, we combined A* search with either BS or ACS by interleaving traditional $\mathrm{A}^{*}$ iterations with BS runs of small width or single iterations of ACS, respectively. Note that we did this combination in a way that avoids redundant expansions of the same nodes, i.e., the methods act on a shared list of open nodes. These anytime algorithms, denoted by $\mathrm{A}^{*}+\mathrm{ACS}$ and $\mathrm{A}^{*}+\mathrm{BS}$ either run until optimality is proven or they are terminated prematurely, in which case a solution of promising quality is returned in combination with an upper bound. To the best of our knowledge, we report proven optimality gaps for larger LCS instances for the first time ever in the literature. Our two anytime algorithms were compared to the well known Anytime Pack Search (APS) and a variant of $\mathrm{A}^{*}+\mathrm{ACS}$ employing the dist heuristic as guidance. All the parameters of the algorithms were tuned w.r.t. both, solution quality and small gaps by using irace. Our computational study showed that $\mathrm{A}^{*}+\mathrm{ACS}$ performs in most cases significantly better than the other algorithms concerning solution quality. New best solutions where found by $A^{*}+\mathrm{ACS}$ for 82 different LCS instance groups from the literature ( $\approx 70 \%$ of all instance groups from the literature), and for the remaining groups, the so far best known results were matched by $\mathrm{A}^{*}+\mathrm{ACS}$ in most cases. Also concerning optimality gaps, $\mathrm{A}^{*}+\mathrm{ACS}$ outperforms the other approaches in most cases or is on par with them. Last but not least, $\mathrm{A}^{*}+\mathrm{ACS}$ usually provides a better anytime behavior in the sense that it earlier produces
better results, and more frequently improves on them over time. Responsible for the success of $A^{*}+A C S$ is the careful selection and combination of strategies and components that proved already successful or promising in earlier works such as pure heuristic beam searches. The most important aspect is that we use, on the one hand, the upper bound UB for steering the classical $A^{*}$ search iterations and, on the other hand, the separate heuristic function EX for guiding the ACS iterations. While UB is required to obtain upper bounds and finally prove optimality, EX approximates the expected LCS length for unrelated random strings and is, for most of the considered benchmark instances, very well suited to lead ACS to promising heuristic solutions. The benefits of EX diminish, however, when instances with strongly related strings are considered, as for example in benchmark set BB. There, EX tends to become a disadvantage.

In future work it may be interesting to consider an approach that analyzes instances in a pre-processing phase in order to determine the most promising strategies and parameters to actually use. For example, one may roughly check the relatedness of the strings in order to decide whether or not EX shall be applied. Moreover, it would be good to find a more efficient way of filtering dominated solutions; this may make filtering actually beneficial also in those cases in which it did not pay off so far, especially within $A^{*}+A C S$. Last but not least, coming up with an effective parallel implementation of our algorithms would be of high practical interest. Finally, note that $\mathrm{A}^{*}+\mathrm{ACS}$ is also a promising starting point for algorithms to solve other variants of the LCS problem such as the constrained LCS problem [20], the repetition-free LCS [1], the doubly-constrained LCS [8], and the restricted LCS [19].

Table 15: BL benchmark. Results when aiming for small gaps (averages over ten instances per row).

## B. Improvements of $\mathrm{A}^{*}+$ ACS Over Other Approaches

Figure 5: Improvement of $\mathrm{A}^{*}+\mathrm{ACS}$ over the competitors in terms of solution quality (in \%) for benchmark set BL. First row: instances with $n=500$. Second row: instances with $n=1000$.

Figure 6: Improvement of $\mathrm{A}^{*}+\mathrm{ACS}$ over the competitors in terms of solution quality (in $\%$ ) for benchmark sets Rat (first column of graphs), Virus (second column of graphics) and Random (last column of graphics).

Figure 7: Improvement of $\mathrm{A}^{*}+\mathrm{ACS}$ over the competitors in terms of solution quality (in \%) for benchmark set ES.

Figure 8: Improvement of $\mathrm{A}^{*}+\mathrm{ACS}$ over the competitors in terms of solution quality (in $\%$ ) for benchmark set BB.

Figure 9: Improvement of $\mathrm{A}^{*}+\mathrm{ACS}$ over the competitors in terms of gaps (in \%) for benchmark set BL. First row: instances with $n=500$. Second row: instances with $n=1000$.

Figure 10: Improvement of $A^{*}+A C S$ over the competitors in terms of gaps (in \%) for benchmark sets Rat (first column of graphs), Virus (second column of graphics) and Random (last column of graphics).

Figure 11: Improvement of $A^{*}+A C S$ over the competitors in terms of gaps (in \%) for benchmark set ES.

Figure 12: Improvement of $A^{*}+A C S$ over the competitors in terms of gaps (in \%) for benchmark set BB.

[^0]:    ${ }^{1}$ We emphasize that it is not necessary to store actual partial solutions $s$ in the nodes. A longest path to any node in the graph starting from the root node and the respective partial solution can be efficiently derived in a backward manner by iteratively identifying a predecessor in which the $l_{v}$-value always decreases by one.

[^1]:    ${ }^{2}$ The source code of Top_MLCS can be found at https://github.com/dxslin/mlcs.
    ${ }^{3}$ All ten instances with $m=10, n=100,|\Sigma|=4$, could be solved by $\mathrm{A}^{*}$ when increasing the memory limit to 40 GB .

[^2]:    ${ }^{4}$ As the best result for a specific group of instances from the literature we took the maximum average solution quality among the reported averages (if any) from $[6,32,14,36,7]$. Most of best results so far are from BS-EX [14].
